The virulence plasmid of the pathogenic actinomycete *Rhodococcus equi* is essential for proliferation of this pathogen in macrophages and the development of disease. The pathogenicity island of this plasmid encodes a family of virulence-associated proteins (Vap), one of which (VapA) is a virulence factor. This paper describes the *vcgAB* operon (*vapA* co-expressed gene), located upstream of the *vapA* operon. Transcription of the *vcgAB* operon gave rise to transcripts with a half-life similar to those determined for other virulence plasmid genes (1.8 min). Transcription started at a promoter similar to the *vapA* promoter, and proceeded through an inefficient terminator into the downstream *vcgC* gene. In addition, *vcgC* is also transcribed from a promoter downstream of *vcgB*. The *vcgAB* and *vapA* operons were coordinately regulated by temperature and pH in a synergistic manner. The latter parameter only affected transcription at higher growth temperatures, indicating that temperature is the dominant regulatory signal. Transcription of the *vcgAB* operon increased 10-fold during the late exponential and stationary growth phases. Transcription was also upregulated during the initial hours following phagocytosis by phagocytic cells. In contrast to *vcgA* and *vcgC*, the *vcgB* gene is conserved in the porcine VapB-encoding plasmid, as well as in pathogenic mycobacteria. The coordinated regulation of *vcgB* and *vapA*, transcription of *vcgB* following phagocytosis and conservation of *vcgB* in pathogenic mycobacteria indicate a role for *vcgB* and the *vcg* genes in the virulence of *R. equi*.

## INTRODUCTION

Although *Rhodococcus equi* was originally identified as a major pathogen of foals, it sporadically infects other animals and is increasingly recognized as an oppor-

tunistic pathogen of predominantly, but not exclusively, immunocompromised humans (Meijer & Prescott, 2004; Muscatello *et al.*, 2007). *R. equi* belongs to a group of actinomycetes that is characterized by a hydrophobic cell envelope containing mycolic acids, which includes *Mycobacterium*, *Corynebacterium* and *Nocardia* species. The majority of *R. equi* infections are associated with pyogranulomatous cavitating pneumonia, although systemic manifestations also occur, including osteomyelitis and cerebral infections (Meijer & Prescott, 2004; Muscatello *et al.*, 2007). *R. equi* is a pathogen of alveolar macrophages that is able to prevent endosomal maturation and the accompanying acidification of the phagolysosome (Hondalus & Mosser, 1994; Toyooka *et al.*, 2005). Proliferation of the pathogen in the endosomal compartment eventually results in the necrotic death of the host cell (Fernandez-Mora *et al.*, 2005; Lührmann *et al.*, 2004). Genomic analysis suggests that

A supplementary figure, showing a VcgB multiple sequence alignment, is available with the online version of this paper.

evolution of virulence occurred through cooption of existing virulence genes and also by gene acquisition via lateral gene transfer (Letek *et al.*, 2010).

All equine and the majority of porcine and human isolates harbour a large plasmid consisting of a highly conserved backbone required for replication and conjugation that is also present in a plasmid harboured by the non-pathogenic *Rhodococcus erythropolis* (Letek *et al.*, 2008; Sekine *et al.*, 2006; Takai *et al.*, 2000). The equine and porcine plasmids differ in a variable region of lower G+C content than the remainder of the plasmid that corresponds to a pathogenicity island. It encodes a family of virulence-associated proteins (Vap), including the virulence factor VapA in equine isolates and its VapB homologue in pig isolates (Byrne *et al.*, 2001; Letek *et al.*, 2008; Ocampo-Sosa *et al.*, 2007; Takai *et al.*, 2000). VapA has been shown to be essential, but not sufficient, for proliferation of *R. equi* in macrophages and development of disease (Giguère *et al.*, 1999; Jain *et al.*, 2003). The *vapA* gene is located in the four-cistronic *vapAICD* operon, which is transcribed from a single promoter that is induced during growth at high temperature and low-to-neutral pH, conditions which resemble the host environment (Byrne *et al.*, 2008; Russell *et al.*, 2004). Interestingly, mRNA processing and the differential mRNA stability of the *vapAICD* transcript result in a greater abundance of the *vapA* transcript relative to that of the three downstream genes (Byrne *et al.*, 2008). The activity of the *vapA* promoter ( $P_{vapA}$ ) is dependent on the presence of the LysR-type transcriptional regulator VirR, which is encoded within the five-cistronic *virR* operon (*virR-orf5-vapH-orf7-orf8*; Fig. 1) located upstream of the *vapAICD* operon (Byrne *et al.*, 2007; Russell *et al.*, 2004). In addition, evidence to date indicates that a response regulator encoded by *orf8* is also required for expression of the *vapAICD* operon (Russell *et al.*, 2004). The activity of the *virR* operon promoter ( $P_{virR}$ ) is negatively autoregulated by VirR, resulting in low-level, constitutive transcription. A second promoter ( $P_{orf5}$ ), located within the *virR* gene (Fig. 1), becomes active during growth at high temperature and low pH, resulting in increased transcription of the four genes located downstream of *virR*, including *orf8* (Byrne *et al.*, 2007).

Located in between the *virR* and *vapA* operons are three genes, *vcgABC* (*orf9*, *orf10*, *orf11*), encoding small proteins of unknown function (Fig. 1). Only one of these, *vcgB*, is conserved in the *vapB* plasmid; *vcgA* is present as a pseudogene, and *vcgC* is absent (Letek *et al.*, 2008). A DNA microarray analysis has shown that *vcgB* and the two non-conserved genes are transcribed following uptake of *R. equi* in macrophages, suggesting they may play a role in virulence (Ren & Prescott, 2003). Here we show that the *vcgB* gene belongs to a gene family conserved in pathogenic mycobacteria that infect phagocytic cells. Its induction upon phagocytosis, synergistic regulation by temperature and pH, coordinated regulation with the *vapA* operon, and conservation in the *vapB* plasmid strongly suggest a role for *vcgB* in pathogenesis.

## METHODS

**Bacterial strains and growth conditions.** Bacterial strains and plasmids used in this study are listed in Table 1. *R. equi* 103, its plasmid-cured derivative and *E. coli* DH5 $\alpha$  were grown in Luria-Bertani (LB) medium (Sambrook & Russell, 2001) or in minimal medium supplemented with 20 mM lactate (LMM), as previously described (Kelly *et al.*, 2002). *R. equi* was routinely grown at 37 °C, pH 5.5 (*vapA*-inducing conditions), or at 30 °C and pH 8.0 (*vapA* non-inducing conditions). Where appropriate, ampicillin at 50  $\mu\text{g ml}^{-1}$ , and apramycin at 30  $\mu\text{g ml}^{-1}$  (*E. coli*) or 80  $\mu\text{g ml}^{-1}$  (*R. equi*), were added. For solid media, agar was added to 1.5% (w/v).

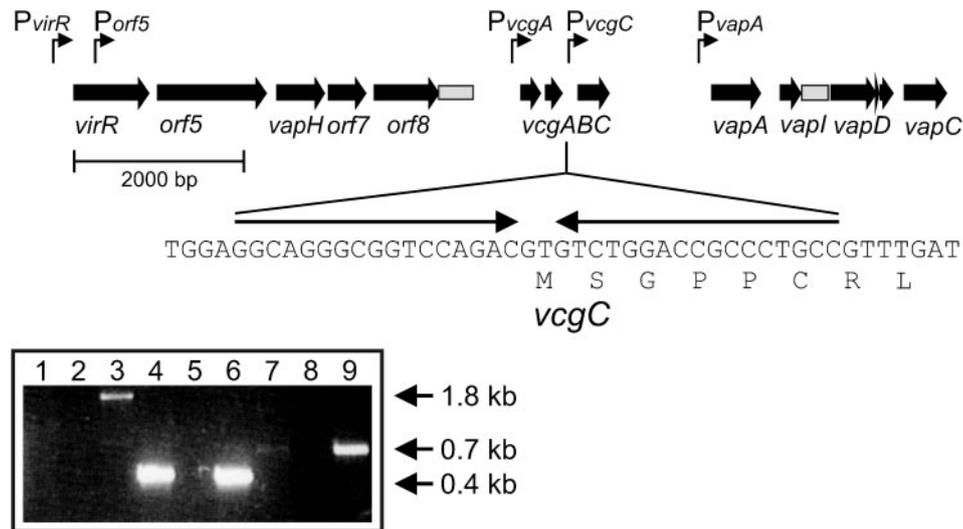

**Plasmid construction.** Promoter probes were constructed using pREV6, as described by Byrne *et al.* (2007). Briefly, serially shortened DNA fragments from the 5' end were produced by PCR using a common reverse primer, VCGCREV, with 8C\_2089F, VCG\_771F or VCG\_389F, and were ligated into the *Clal* site of pREV6 to produce pP1, pP2 and pP3, respectively. Construct orientation was checked by digestion with appropriate restriction enzymes and confirmed by double-strand sequencing.

pVcgABC, containing the t-tag downstream of *vcgC*, was used for the generation of a deleted version to locate the t-tag within *vcgA*. For this, 1  $\mu\text{g}$  pVcgABC was double-digested with *ApaI* and *NdeI* restriction enzymes (New England Biolabs). Non-compatible overhanging ends were repaired with the Klenow fragment of DNA polymerase I. Thirty femtomoles of repaired product was recircularized with T4 DNA ligase and transformed into *E. coli* DH5 $\alpha$ . Deletions were checked by PCR using primers 8C\_2089F and VCGCREV, by digestion with relevant restriction enzymes and sequencing. In this case, the t-tag was used as a reporter for the comparison of the expression levels of *vcgA* and *vcgC*. Reverse transcriptase quantitative PCR (RT-qPCR) analysis was performed as above but using the specific primer t-tag167R for the reverse-transcription step.

pUO9S was constructed by cloning an 872 bp PCR product containing  $P_{vcgA}$ , the 3' end of *orf8* and the 5' end of *vcgA* into the *EcoRV* site of pBluescript KSII+.

**RNA isolation.** RNA was isolated from *R. equi* grown *in vitro* as described previously (Russell *et al.*, 2004). *R. equi* RNA was isolated from macrophages following phagocytosis of the pathogen using a guanidine thiocyanate-based lysis buffer [4 M guanidine thiocyanate, 0.5% (w/v) sodium *N*-lauryl sarcosine, 25 mM sodium citrate, 0.1 M  $\beta$ -mercaptoethanol] as described elsewhere (Butcher *et al.*, 1998; Rohde *et al.*, 2007). Samples were vortexed and passed through a needle to shear macrophage DNA and to reduce viscosity. Intracellular bacteria were recovered by centrifugation. Pelleted bacteria were lysed using TRIzol (Sigma), and physically disrupted with zirconia beads in a MagNA Lyser instrument (Roche). Total RNA was isolated by chloroform extraction, followed by DNA digestion with Turbo DNase (Ambion) and application to a Qiagen RNeasy column with a second, in-column, DNA digestion with the RNase-free Dnase, as previously described (Miranda-CasoLuengo *et al.*, 2005).

**Reverse transcription and PCR.** Reverse-transcriptase reactions using hexameric random primers (Promega) were performed with 1 U ImProm-II reverse transcriptase (Promega) following the manufacturer's recommendations with 100 ng total RNA as template in a final volume of 20  $\mu\text{l}$ . The resulting product was used in either an end point PCR or an RT-qPCR. For the former, 2  $\mu\text{l}$  of the reaction mixture was used as template for GoTaq Flexi DNA polymerase (Promega), as described by the manufacturer. For RT-qPCR, the product was amplified using the QuantiTect SYBR Green real-time kit following the manufacturer's instructions (Qiagen). Reaction mixtures were subjected to 40 cycles of 95 °C for 15 s,

**Fig. 1.** Transcriptional organization of the *vcgABC* gene cluster and flanking *virR* (Byrne *et al.*, 2007) and *vapA* (Byrne *et al.*, 2008) operons of the VapA virulence plasmid of *R. equi*. Promoter location is shown by hooked arrows and by 'P'. The grey boxes downstream of *orf8* and *vapI* represent a *vap* pseudogene (Russell *et al.*, 2004) and the frame-shifted 5' end of *vapI* (Polidori & Haas, 2006), respectively. The nucleotide sequence of a 17 bp inverted repeat downstream of *vcgB* and partially overlapping the 5' end of *vcgC* is delineated by arrows. The insert shows the results of the reverse transcriptase analysis of the *vcgAB* operon using the oligonucleotide pairs 08F/09R (predicted size 1880 bp) complementary to *orf8* and *vcgA* (lanes 1–3), 09F/010R (predicted size 477 bp) complementary to *vcgA* and *vcgB* (lanes 4–6), and 010F/011R (predicted size 738 bp) complementary to *vcgB* and *vcgC* (lanes 7–9). Lanes 1, 4 and 7, 2  $\mu$ l of the reverse transcriptase reaction (cDNA); lanes 2, 5 and 8, reaction without reverse transcriptase; lanes 3, 6 and 9, reaction using genomic DNA as template.

60 °C for 30 s and 72 °C for 30 s in a LightCycler (Roche) with temperature transition rates of 20 °C s<sup>-1</sup>. Melting curve analysis was performed at 50–95 °C (temperature transition 0.2 °C s<sup>-1</sup>), with continuous fluorescence detection following amplification. Cycle threshold ( $C_T$ ) values were obtained and used to calculate the number of RNA copies per microgram of total RNA using a standard curve of known amounts of DNA target with  $r^2$  coefficients greater than 0.997 in the range of  $5 \times 10^3$  to  $5 \times 10^8$  molecules per reaction. 16S rRNA was used as a control to compare the amount of RNA in each reaction.

A relative approach was used for the quantification of intramacrophage *R. equi* transcript levels. Normalization of gene expression was performed by the  $(1+E)^{-\Delta C_T}$  method (Pfaffl, 2004) using 16S rRNA as an internal control. Efficiencies ( $E$ ) of amplification were determined for each pair of primers by running standard curves with  $r^2$  coefficients greater than 0.99 in the range of  $10^2$  to  $10^5$  *R. equi* genomic equivalents using the formula  $E = (10^{(1/m_{PCR})} - 1)$ , where  $m_{PCR}$  is the slope of the standard curve.  $E$  values for 16S rRNA, *vcgA*, *vcgB* and *vcgC* were 1.03, 1.03, 0.87 and 0.93, respectively. The data reported in this paper represent the results of three independent

experiments in which each sample was analysed in duplicate. The sequences of oligonucleotides used for RT-qPCR are listed in Table 2.

**mRNA half-life determination.** The rate of mRNA decay was determined as described previously (Byrne *et al.*, 2008). Briefly, transcription was halted during mid-exponential growth by addition of rifampicin (200 µg ml<sup>-1</sup>). The half-life of specific transcripts was determined by RT-qPCR followed by linear regression.

**Fluorescent primer extension and DNA sequencing.** WellRED D4-labelled oligonucleotide D4-ORF9PEx (Table 2), complementary to sequences 20–39 bp downstream of the initiation codon of *vcgA*, was used in the primer extension reaction to find the transcriptional start site of the *vcgAB* operon, as previously described (Byrne *et al.*, 2007). Briefly, 2 µg total RNA was reverse-transcribed using ImProm-II reverse transcriptase (Promega), and the RNase-treated product was combined with DNA Size Standard kit 600 (Beckman Coulter) and analysed with a Beckman CEQ 8000 Genetic Analysis System following the manufacturer's directions (Beckman Coulter). In parallel, a dideoxy sequencing reaction with the ORF9PEx primer was carried out using *NheI*-digested pUO9S as template and the GenomeLab DTCS kit as directed by the manufacturer (Beckman Coulter). pUO9S harbours an 872 bp PCR fragment covering the intergenic region of *orf8* and *vcgA* obtained with VP9445F and ORF9PEx primers and cloned into the pDrive vector using the Qiagen PCR cloning kit as directed by the manufacturer (Qiagen). D4-labelled primer extension products were added to the dideoxy sequencing products prior to analysis with the Beckman CEQ 8000 Genetic Analysis System to identify the transcriptional start site.

**VapA quantification.** *R. equi* was harvested by centrifugation (10 min, 4000 g, 4 °C) and resuspended in 100 mM Tris/HCl (pH 8.0) and 10 mM EDTA (pH 8.0). Cells were lysed by three passages through a French press and cell debris was removed by

centrifugation (10 min, 14 000 g, 4 °C). Soluble cell extracts were boiled for 10 min in SDS [62.5 mM Tris/HCl (pH 6.8), 10% (v/v) glycerol, 2% SDS, 5% 2-mercaptoethanol, 0.02% bromophenol blue], and applied to a denaturing polyacrylamide gel. Proteins were subsequently transferred onto a PVDF membrane (Immobilon-P, Millipore) according to the manufacturer's instructions. Immunoblot analysis was performed with a chemiluminescent Western blot analysis system (Lumi-Light Western Blotting Substrate, Roche). Monoclonal antibody against VapA (Mab 10G5; provided by S. Takai, Kitasato University, Towada, Japan) was used for immunoblotting procedures. Protein was quantified using the Bio-Rad Multi-Imaging system and the Bio-Rad Quantity One software package.

**Infection of J774A.1 cells.** Bacteria grown in LMM were centrifuged (10 min, 3220 g) and washed twice with cation-free PBS (Sigma). Murine macrophage-like cells J774A.1 were seeded at  $6 \times 10^5$  cells ml<sup>-1</sup> in 6 cm tissue culture plates (Sarstedt) and cultured at 37 °C in 5% CO<sub>2</sub> overnight. Monolayers were washed once with pre-warmed phagocytosis buffer [0.1% (w/v) gelatin, equal amounts of Medium 199 and Dulbecco's modified Eagle's medium (DMEM)] (Hondalus *et al.*, 1993), and the medium was replaced with phagocytosis buffer containing 5% mouse serum (Sigma) as a source of complement. J774A.1 cells were infected with *R. equi* at an m.o.i. of 20. Infections were initiated by centrifugation (160 g, 3 min) of bacteria onto confluent monolayers to synchronize the internalization. Plates were incubated for 45 min at 37 °C in 5% CO<sub>2</sub>. Monolayers were washed three times with warm phagocytosis buffer (37 °C) to remove unbound bacteria and incubated for a further 15 min to allow internalization of the attached bacteria. Monolayers were washed again with warm phagocytosis buffer. Phagocytosis buffer was subsequently replaced with DMEM supplemented with 10% (v/v) fetal calf serum, 4 mM L-glutamine, 1% non-essential amino acids and 10 µg gentamicin ml<sup>-1</sup> (this time point was denominated *t*=0). Infected monolayers were harvested at different time points between 2

†This oligonucleotide was used unmodified and fluorescently labelled with WellRed D4 dye for sequencing and primer extension, respectively.

and 48 h. Medium was replaced after 24 h with fresh medium containing 10 µg gentamicin ml<sup>-1</sup>.

**Enumeration of intracellular *R. equi*.** The intracellular proliferation of *R. equi* was assessed by quantitative PCR (qPCR). Monolayers washed twice with PBS were scraped at indicated times post-infection ( $t=0, 2, 24$  and 48 h), spun down, and resuspended in 10 mM Tris/HCl, pH 8.0. Harvested samples were heated at 99 °C for 10 min, and then spun down briefly to pellet cellular debris. qPCR amplifying 16S rRNA was performed as described above.  $C_T$  values were used to calculate the *R. equi* cell number using a standard curve of known amounts of bacteria with  $r^2$  coefficients greater than 0.9952 in the range of  $1 \times 10^2$  to  $1 \times 10^6$  bacteria per reaction.

**Phylogenetic analysis.** An alignment of the VcgB (Orf10) proteins and their mycobacterial homologues (Supplementary Fig. S1) was constructed using CLUSTAL\_X (Larkin *et al.*, 2007), and subsequently used to infer phylogenetic relationships using the programs supplied in the PHYLIP v3.68 software suite (Felsenstein, 1989). A distance matrix was calculated with PROTDIS using the Jones–Taylor–Thornton model (Jones *et al.*, 1992). An unrooted phylogenetic tree was subsequently constructed via neighbour joining as implemented in the NEIGHBOR program.

**RNA structure analyses.** RNA structure and minimum free energy of prediction were done using the RNAfold of the Vienna RNA Server (<http://rna.tbi.univie.ac.at/>).

**Statistical analyses.** Statistical analyses were performed by Student's *t* test for paired values. Differences were considered significant at  $P < 0.05$ .

**Gene nomenclature.** The *vapB*-containing plasmid pVAPB1539 (accession no. AM947676) was recently annotated and the *vapA* plasmid pVAPA1037 (accession no. AM947677) was reannotated (Letek *et al.*, 2008). The *orf9* and *orf11* genes of the latter plasmid were denoted pVAPA\_0560 and pVAP\_0580. The *orf10* genes on the two plasmids were denoted pVAPB\_0570 and pVAPA\_0570, respectively. Since the *orf9*, *10* and *11* genes are regulated in a manner similar to the virulence gene *vapA*, we propose to rename these genes to *vcgA*, *vcgB* and *vcgC*, respectively (*vapA* co-expressed gene).

## RESULTS

### *vcgB* is conserved in pathogenic *Mycobacterium* species

A hallmark of the pathogenicity island of the *R. equi* virulence plasmid is the large proportion of genes that are unique to this pathogen, including the *vcgA* and *vcgC* genes. However, comparison by BLASTP and PSI-BLAST of VcgB with protein sequences deposited in GenBank revealed extensive similarities to a family of small mycobacterial proteins (Supplementary Fig. S1). In addition to these, VcgB homologues are also present, but not annotated, in the genomes of *Mycobacterium tuberculosis* H37Rv, *Mycobacterium bovis* BCG and *Mycobacterium abscessus*. The last species contains two *vcgB* homologues, which are separated by 3 kb. Interestingly, *vcgB* homologues were not found in species other than in the genus *Mycobacterium*, and, with the exception of *Mycobacterium smegmatis*, all are pathogenic *Mycobacterium* species.

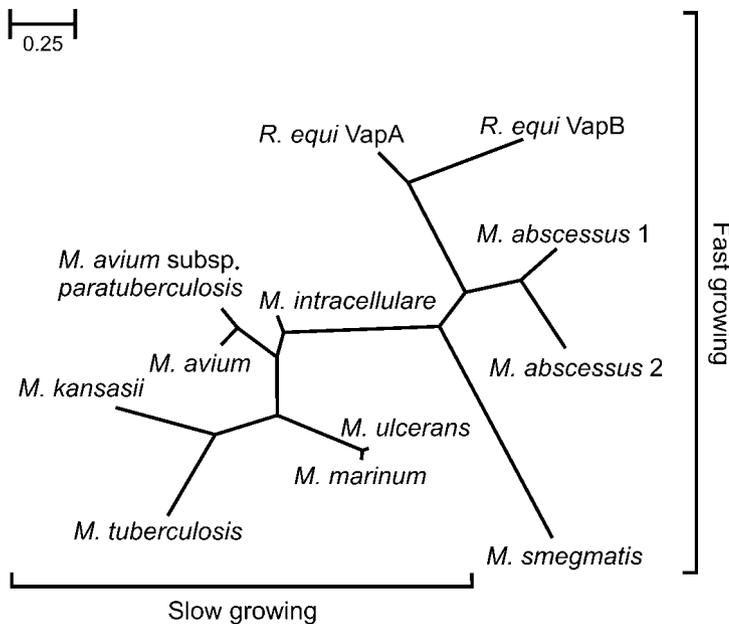

A phylogenetic analysis showed that the VcgB homologues grouped into two clusters (Fig. 2). Cluster 1 contained the *Mycobacterium avium*, *M. avium* subsp. *paratuberculosis*, *Mycobacterium intracellulare*, *Mycobacterium ulcerans*, *Mycobacterium marinum*, *Mycobacterium kansasii* and *M. tuberculosis* proteins, whereas the *R. equi* proteins grouped with those of *M. smegmatis* and *M. abscessus*. Cluster 1 represents slow-growing mycobacterial species, whereas the species present in the second cluster are fast-growing. The topology of the VcgB phylogenetic tree closely matches that of the 16S rRNA genes of these species (Devulder *et al.*, 2005).

### The *vcgAB* genes form an operon

The conservation of the *vcgB* gene in pathogenicity islands of *R. equi* strains with different host specificities as well as in pathogenic mycobacteria suggests that this gene may play a role in the interaction with the host. The regulation and transcriptional organization of this gene was therefore analysed in greater detail. The *vcg* gene cluster is located between the *virR* and *vapA* operons (Fig. 1). The close proximity of *vcgA* to *vcgB* (68 bp) suggests that they may be cotranscribed. In contrast, *vcgB* is separated by 203 bp from *vcgC*. This relatively large intergenic region between *vcgB* and *vcgC* contains a 17 bp inverted repeat that may form a stable RNA structure with a free energy of  $-39$  kcal mol<sup>-1</sup> ( $-163$  kJ mol<sup>-1</sup>), which masks the initiation codon and ribosome-binding site of *vcgC* (Fig. 1). This RNA structure is followed by three uridines, thus resembling an intrinsic terminator (Platt, 1986). To investigate the transcriptional organization of these genes, mRNA was isolated and reverse-transcribed from *R. equi* grown under *vapA*-inducing conditions. The resulting cDNA was amplified by PCR using oligonucleotide primers (Table 2) complementary to sequences in adjacent genes (Fig. 1). Strong amplification was observed when the *vcgA*–*vcgB* pairs were used, whereas only a weak signal was detected when the *vcgB*–*vcgC* primer pair was deployed. These data demonstrate that the *vcgAB* genes form an operon, with probable read-through into *vcgC*. An amplicon was not observed when oligonucleotides were used that were complementary to *orf8*, the last gene of the *virR* operon, and *vcgA*, showing that the *vcg* gene cluster is not dependent on promoters in the *virR* operon (Fig. 1).

### The *vcgABC* cluster contains an internal promoter

The RT-PCR experiments clearly showed that *vcgA* and *vcgB* are cotranscribed, whereas the weak signal obtained following RT-PCR using the *vcgB*–*vcgC* primer pair suggested that read-through from *vcgB* into the downstream *vcgC* gene might occur. To examine whether this was the case, the ability of sequences upstream of *vcgC* to drive transcription of *vcgC* was examined using the promoter probe vector pREV6 (Fig. 3a). This vector contains a small DNA fragment (t-tag) located in between two transcriptional terminators that is absent in the *R. equi*

**Fig. 2.** Phylogenetic relationships of VcgB (pVAPA\_0570 and pVAPB\_0570) of the VapA and VapB virulence plasmids (Letek *et al.*, 2008; Takai *et al.*, 2000), respectively, and homologous proteins in *Mycobacterium* species. The tree is based on a distance analysis using protein sequences from *M. avium* MAV5198 (NC\_008595), *M. avium* subsp. *paratuberculosis* MAP3516 (Li *et al.*, 2005), *M. intracellulare* MintA\_22949 (ZP\_05227808), *M. kansasii* MkanA1\_02227 (ZP\_04746761), *M. marinum* MMAR0314 (Stinear *et al.*, 2008), *M. smegmatis* MSMEG5646 (NC\_008596), *M. tuberculosis* MT0124 (Fleischmann *et al.*, 2002) and *M. ulcerans* MUL4808 (Stinear *et al.*, 2007). The proteins from *M. abscessus* are not annotated; protein sequences were derived from nucleotides 2 763 298–2 763 170 (in between MAB2716c and MAB2715c) and 2 766 687–2 766 553 (in between MAB2718c and MAB2717c) of the *M. abscessus* genome (NC\_010397). The *M. tuberculosis* H37Rv protein is not annotated; the protein sequence is derived from nucleotides 139 965–140 141 (in between Rv0115 and Rv0116c) of the *M. tuberculosis* H37Rv genome (Cole *et al.*, 1998).

genome and virulence plasmid (Byrne *et al.*, 2007). Introduction of the complete *vcgABC* cluster and the *orf8–vcgA* intergenic region in pREV6 resulted in transcription of the t-tag, demonstrating the presence of an active promoter. Deletion of the *orf8–vcgA* intergenic region, as well as *vcgA* and the 5' end of *vcgB*, reduced transcription twofold. Further deletion of *vcgB* and the 5' end of *vcgC* abolished transcription of the t-tag completely (Fig. 3b). These data show that read-through from a promoter ( $P_{vcgA}$ ) upstream of *vcgA* into *vcgC* does occur, despite the presence of a putative terminator, since deletion of this promoter reduced transcription of the t-tag by 50%. The fact that transcription was not abolished completely demonstrates the presence of a second promoter ( $P_{vcgC}$ ) that drives transcription of the *vcgC* gene.

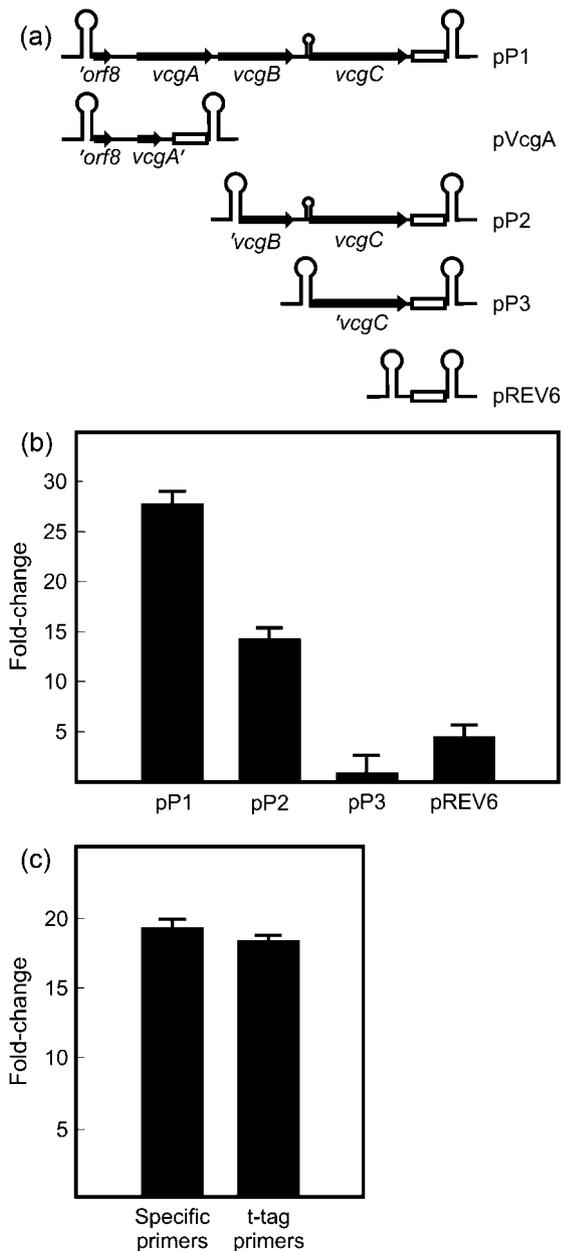

### Transcriptional termination occurs between *vcgAB* and *vcgC*

The *vcgAB–vcgC* intergenic region contains a putative terminator structure, although read-through past this putative terminator occurs. To examine the relative transcription levels of *vcgAB* and *vcgC* and to determine whether there is termination in between the former and latter, the transcript levels of *vcgA* relative to *vcgC* were determined. Using primers complementary to *vcgA* and *vcgC*, a 20-fold difference in transcript level was detected (Fig. 3c). To rule out that this difference was due to a difference in reverse transcription efficiency, the t-tag in pREV6 was placed either behind the  $P_{vcgA}$  promoter (pVcgA) or behind both  $P_{vcgA}$  and  $P_{vcgC}$  (pP1). In this

case, the effects of differential reverse transcription are negated since the same template for reverse transcription is used. As before, a 20-fold difference in transcription was observed when comparing the former with the latter (Fig. 3c). These data thus demonstrate that the *vcgAB* transcripts are at least 20-fold more abundant than the *vcgC* transcript. In addition, they show that the putative terminator downstream of *vcgAB* is approximately 90% effective.

### Growth phase-dependent transcription of the *vcg* genes

*R. equi* was grown under *vapA*-inducing conditions, and *vcgABC* transcript levels were determined during the exponential (0–12 h) and stationary (12–48 h) growth phases (Fig. 4). The transcript levels of *vcgAB* increased approximately 10-fold during the late exponential and stationary growth phases compared with early exponential growth. Similarly, *vcgC* levels increased approximately 10-fold during the late exponential phase, but subsequently fell to levels similar to those at the start of the experiment. The half-lives of the *vcgA* ( $1.7 \pm 0.2$  min), *vcgB* ( $1.8 \pm 0.2$  min) and *vcgC* ( $1.7 \pm 0.4$  min) transcripts were similar to those reported for the genes of the *virR* operon (1.8 min) (Byrne *et al.*, 2007) and the *vapICD* genes of the *vapA* operon (Byrne *et al.*, 2008). In contrast, the *vapA* transcript is more stable, with a reported half-life of 7.5 min (Byrne *et al.*, 2008). The short half-lives of the *vcg* transcripts show that the 10-fold increase in *vcgAB* and *vcgC* transcript levels was not due to accumulation of a relatively stable transcript during growth, but instead was

**Fig. 3.** Determination of the  $P_{vcgA}$  and  $P_{vcgC}$  promoter activities by RT-qPCR. (a) Schematic representation of inserts in the promoter probe vector pREV6. Hairpin structures represent transcriptional terminators: large hairpin structures are the transcriptional terminators of pREV6; the small hairpin structure indicates the position of the putative terminator downstream of *vcgB*. Genes and their direction of transcription are indicated by black arrows. The white box represents the transcription tag (t-tag). The transcription level of the t-tag was measured by RT-qPCR. (b) Relative mRNA transcript levels of the t-tag in *R. equi* harbouring plasmids pP1, pP2, pP3 and pREV6. Fold changes were obtained by calibrating against the promoterless probe (pP3). (c) mRNA transcript levels of *vcgA* relative to *vcgC*. Transcript levels were determined using primers specific to *vcgA* and *vcgC* and RNA isolated from *R. equi* 103, or using primers specific for the t-tag

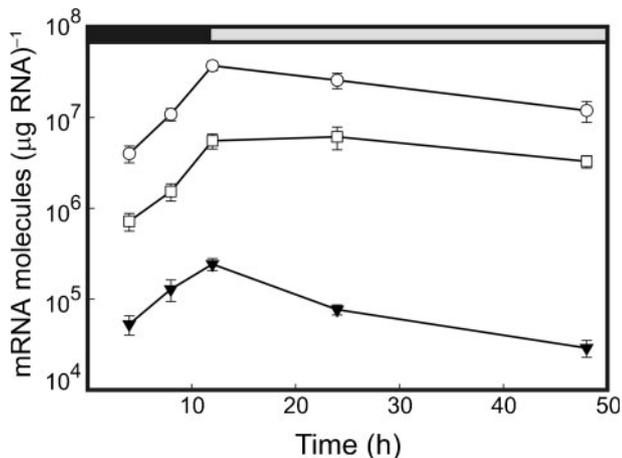

and RNA isolated from *R. equi* harbouring either pP1 or pVcgA. t-tag transcription of pP1 depends on the activities of the  $P_{vcgA}$  and  $P_{vcgC}$  promoters as well as the efficiency of the putative terminator downstream of *vcgB*. t-tag transcription of pVcgA depends on the activity of the  $P_{vcgA}$  promoter.

due to an increased transcription of the *vcg* operon during the mid- to late-exponential growth phase that continued into the stationary phase for the *vcgAB* genes, but not for *vcgC* (Fig. 4).

### Co-regulation of the *vcgAB* and *vapA* operons: synergistic effect of high temperature and low pH

Transcription of the *vapA* operon, which is located downstream of the *vcg* genes, is induced during growth at low pH and high temperature, resembling the conditions encountered by *R. equi* in the host (Takai *et al.*, 1996). To compare the regulation of the *vcgAB* and *vapA* operons, their transcription was determined following growth under *vapA*-inducing (pH 5.5, 37 °C) and non-inducing growth conditions (pH 8.0, 30 °C) by determining the mRNA levels of *vcgB* and *vapA* (Fig. 5). The *vcgB* and *vapA* mRNA levels under the former growth conditions were, respectively, 20- and 100-fold higher compared with the latter, demonstrating that transcription of the *vcg* operon is also induced by low pH and high growth temperature (Fig. 5a). To determine the relative contributions of each environmental parameter, temperature and pH were varied individually. Changing the pH of the medium from pH 8.0 to pH 5.5 while keeping the temperature at 30 °C resulted in relatively little change in the transcription level of either operon compared with non-inducing growth conditions. In contrast, an increase in growth temperature from 30 to 37 °C, while keeping the pH at 8, had a more significant, yet modest, effect (respectively, eight- and 32-fold increases in *vcgB* and *vapA* mRNA levels). The data thus show that pH only significantly affected transcription of the *vcg* and *vapA* operons at 37 °C but not at 30 °C, whereas growth temperature affected transcription at both low and high pH. However, it is clear that a simultaneous reduction in pH and increase in temperature had a synergistic effect on the transcription of the *vcgAB* and *vapA* operons.

To further validate these results, the expression levels of VapA protein were determined using monoclonal antibodies directed against VapA (Fig. 5b). The VapA expression pattern was the same as the *vapA* transcript levels, VapA protein levels increased by approximately 100-fold when comparing non-inducing with inducing growth conditions. Furthermore, a decrease in pH and increase in temperature of the growth medium had a synergistic effect on the VapA protein expression levels, while pH did not significantly affect expression at 30 °C.

**Fig. 4.** Absolute quantification of the *vcgA* (○), *vcgB* (□) and *vcgC* (▼) transcripts of the virulence plasmid of *R. equi* during growth in LB medium at pH 5.5, 37 °C. Shown are the means  $\pm$  SD (error bars) of three independent experiments in which each sample was analysed in duplicate. The black and grey bars represent, respectively, the exponential and stationary growth phases of *R. equi*.

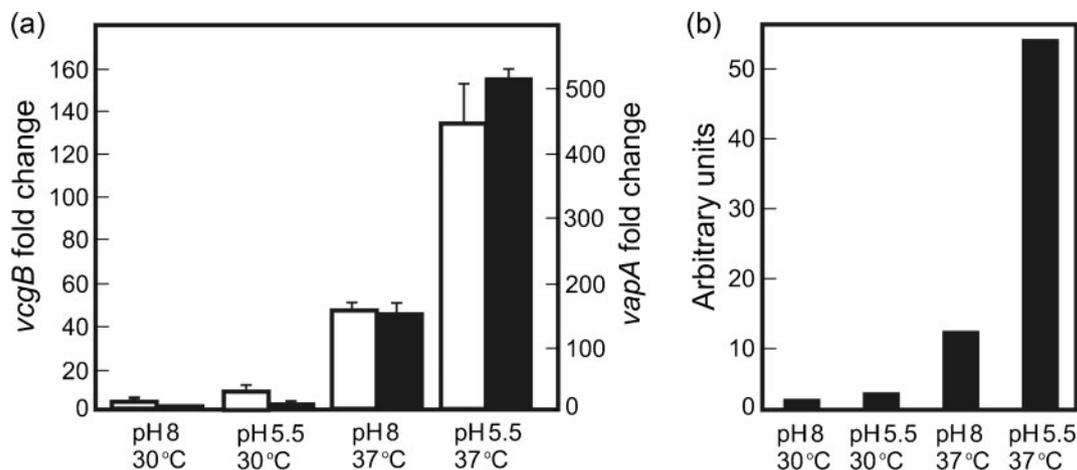

### The *vcgAB* operon and *vcgC* are transcribed in macrophages

A DNA microarray study has shown that the genes of the pathogenicity island, including the *vcg* genes, are transcribed in macrophages, although these microarray data have not been validated by other techniques (Ren & Prescott, 2003). To date, no temporal transcription

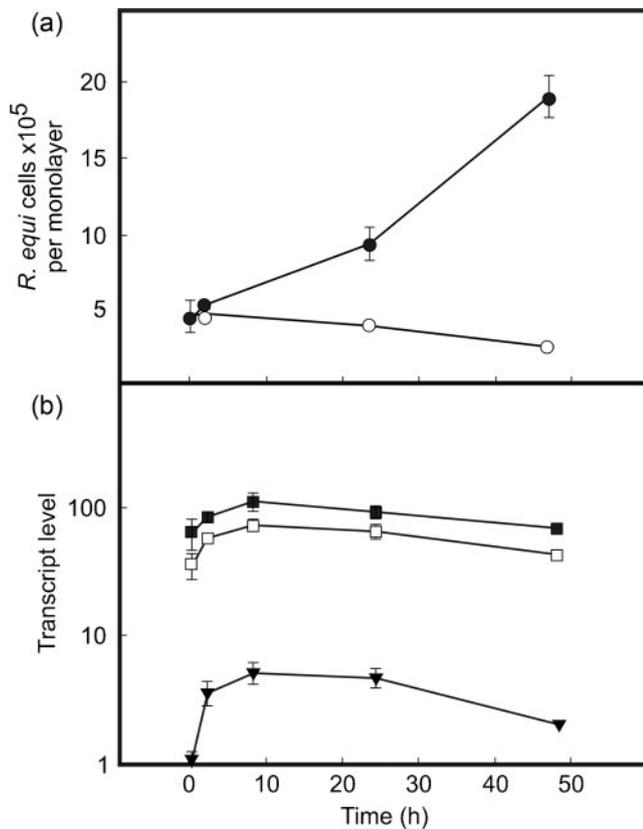

profile of these genes, or of any other genes, following uptake of *R. equi* by macrophages, has been determined. To examine the regulation of the *vcg* genes *in vivo*, macrophages were infected with virulent and avirulent *R. equi* pregrown on minimal medium supplemented with lactate at 37 °C, pH 7. As expected, virulent *R. equi* proliferated within macrophages, whereas the avirulent plasmid-free strain did not (Fig. 6a). RNA was extracted over a 48 h period, and the relative transcription levels of *vcgA*, *vcgB* and *vcgC* were determined (Fig. 6b). Transcript levels increased two- to fivefold in the initial 8 h following infection and declined to the initial levels in the subsequent 40 h.

### The promoter of the *vcgAB* operon is similar to the *vapA* and *virR* operon promoters

Since the *vcgAB* operon is regulated in a similar manner to the *vapA* operon, it seems likely that the promoters of the two are similar. To compare the *vcgAB* promoter with previously identified *R. equi* promoters (Byrne *et al.*, 2007; Russell *et al.*, 2004), the transcriptional start site of the *vcgAB* operon was determined by primer extension using the fluorescently labelled oligonucleotide D4-ORF9PE<sub>x</sub>, which was hybridized to mRNA isolated from *R. equi* grown under *vapA*-inducing conditions. Reverse transcription resulted in a major primer extension product with an estimated size of 331 bp (Fig. 7a). The transcriptional start site inferred from the major extension product mapped to a cytidine 292 bp upstream of the *vcgA* start codon (C<sub>292</sub>). In addition, a shorter, minor extension product was observed with an estimated size of 257 bp, which

**Fig. 5.** Expression of *vcgB* and *vapA* during the late exponential growth phase of *R. equi* on LB medium at pH 5.5 or 8.0 and at 30 or 37 °C. Transcript levels were normalized to levels of 16S rRNA and fold changes obtained against the expression levels under non-inducing conditions of growth (pH 8.0 and 30 °C). (a) Fold changes for *vcgB* (white bars) and *vapA* (black bars). Transcript levels were normalized to levels of 16S rRNA and fold changes obtained against the transcription levels under non-inducing conditions of growth (pH 8.0 and 30 °C). Shown are the means  $\pm$  SD (error bars) of three independent experiments in which each sample was analysed in duplicate. (b) Expression levels of VapA protein following Western blotting using mAb 10G5 monoclonal antibodies. Equal amounts of protein were added to each lane.

**Fig. 6.** Transcriptional profile of the *vcg* gene cluster of the *R. equi* virulence plasmid following infection of the murine macrophage-like cell line J774A.1. Monolayers were infected with *R. equi*. Following a 45 min incubation to allow phagocytosis, monolayers were washed and treated with gentamicin to kill remaining extracellular bacteria ( $t=0$ ). Intracellular bacteria were enumerated by qPCR using the 16S rRNA gene as template. (a) Intracellular proliferation of isogenic strains *R. equi* 103<sup>+</sup> (●) and *R. equi* 103<sup>-</sup> (○). (b) Transcription levels of *vcgA* (■), *vcgB* (□) and *vcgC* (▼) relative to the levels of 10<sup>6</sup> molecules of 16S rRNA. Values are shown as means  $\pm$  SD (error bars).

corresponded to a thymidine 219 bp ( $T_{219}$ ) upstream of the *vcgA* initiation codon (Fig. 7b, c).

The  $-10$  region upstream of  $C_{292}$  shares significant sequence similarity (Fig. 7d) with the promoter recognized by the principal sigma factor  $\sigma^{hrdB}$  of *Streptomyces coelicolor* (Buttner *et al.*, 1990; Kang *et al.*, 1997). In addition, this region is similar to those of the previously identified  $P_{virR}$  and  $P_{vapA}$  promoters (Fig. 2) of the *virR* and *vapA* operons (Byrne *et al.*, 2007; Russell *et al.*, 2004). As was observed previously for the  $P_{virR}$  and  $P_{vapA}$  promoters, the  $-35$  region upstream of  $C_{292}$  does not share significant similarity with that of the  $\sigma^{hrdB}$  promoter. However, the  $-35$  region of the *vapA* promoter and that of  $C_{292}$  are 56% identical, with three out of the four mismatches being transitions (89% similarity). In contrast, the region upstream of the minor extension product ( $T_{219}$ ) does not

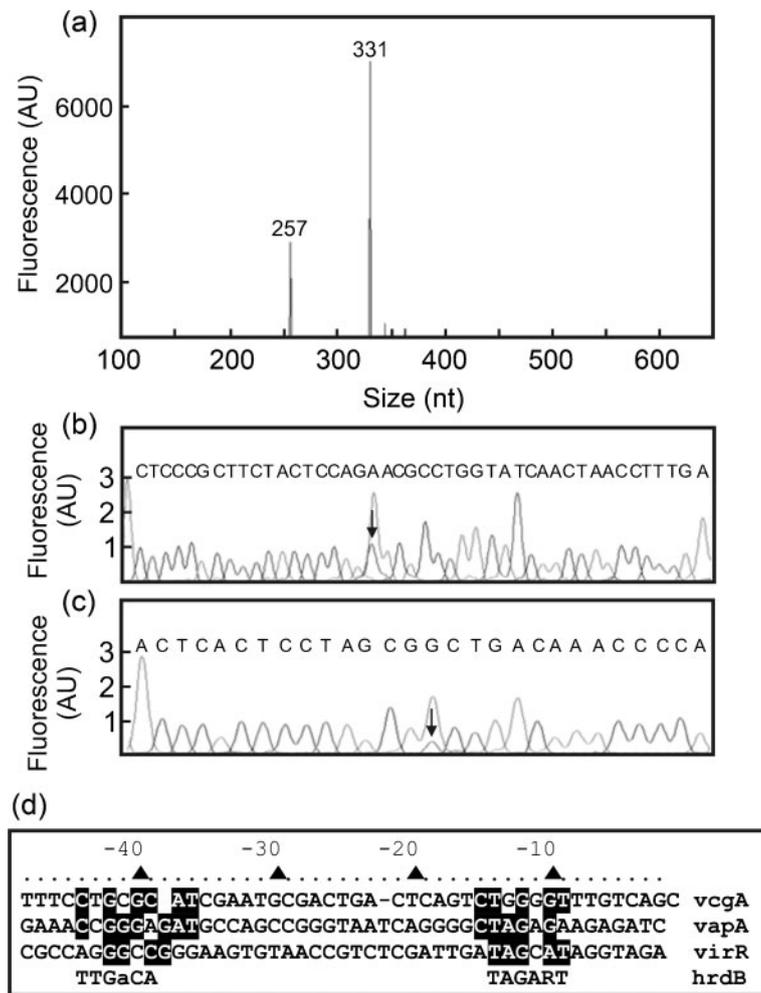

share any similarities with previously identified *R. equi* promoters.

## DISCUSSION

The *vcgAB* operon is, after the *virR* and *vapA* operons, the third operon of the pathogenicity island to be described in detail (Byrne *et al.*, 2007, 2008). Transcription of this operon terminates in an inefficient terminator downstream of *vcgB*, allowing some read-through from *vcgAB* into the downstream *vcgC* gene, which also has its own promoter. The RNA structure forming the *vcgAB* terminator obscures both the *vcgC* start codon and ribosome-binding site. This, together with the 20-fold lower *vcgC* mRNA levels compared with *vcgAB*, suggests that *vcgC* is very poorly expressed.

The transcriptional regulation of the *vcgAB* operon was identical to that of the *vapA* operon. Although both temperature and pH control their transcription, the latter only had a significant effect at high temperatures. In contrast, a temperature increase induced transcription of both operons, regardless of pH. Temperature therefore seems to be the primary environmental parameter that controls transcription of *vcgAB* and *vapA*, and, based on the VapA protein profiles, expression of the pathogenicity island genes. The role of temperature as the primary determinant to control virulence gene expression is common to many pathogens. Although the mechanisms to detect temperature are diverse, they often rely on detection of perturbation of the conformation of biomolecules such as RNA or lipids (Klinkert & Narberhaus, 2009). The mechanism used by *R. equi* to control temperature-dependent virulence gene expression remains unknown. Interestingly, the effect of pH and temperature on transcription of the *vapA* and *vcgAB* operons is not independent, but is clearly synergistic. This strongly suggests a common, as-yet-unidentified, denominator in the transduction of these unrelated signals to the transcriptional apparatus.

The transcript levels of the *vcgAB* operon increased 10-fold at the end of the growth phase and remained high throughout the stationary phase. This suggests that the growth phase may be an important trigger for virulence gene expression, as has been observed in other pathogens, including *Vibrio cholerae*, *Legionella pneumophila* and *Yersinia enterocolitica* (Hovel-Miner *et al.*, 2009; Iriarte *et al.*, 1995; Nielsen *et al.*, 2006). *R. equi* grows rapidly in minimal media supplemented with, for example, volatile fatty acids, or in manure-enriched soils (Hughes & Sulaiman, 1987; Kelly *et al.*, 2002), whereas in macrophages, growth is relatively slow, which may be due to a restriction of nutrients such as iron (von Bargen *et al.*, 2011). Furthermore, populations of slow-growing or stationary phase bacteria are more vulnerable to being wiped out by phagocytic cells or predatory protozoa than fast-growing bacterial populations. Increased transcription

**Fig. 7.** Determination of the transcriptional start site of the *vcg* operon of *R. equi*. Fluorescent primer extension was carried out with the D4-labelled primer and 2  $\mu$ g total cellular RNA extracted from *R. equi* grown under inducing conditions (37  $^{\circ}$ C and pH 5.5). (a) Fragment length analysis of the D4-labelled primer extension product combined with DNA size standards. (b, c) Comigration of extension products with a dideoxy sequencing reaction; arrows indicate the complementary base of the 257 bp (b) and 331 bp (c) extension products. (d) Alignment of the promoters of the *vcgAB* operon, the *vapA* operon (Russell *et al.*, 2004) and the *virR* operon (Byrne *et al.*, 2007). The consensus sequence of the  $\sigma^{hrdB}$ -dependent *S. coelicolor* promoter (Buttner *et al.*, 1990; Kang *et al.*, 1997) is shown for comparison. Conserved nucleotides in the  $-10$  and  $-35$  regions are shown as white letters on a black background.

of virulence genes during periods of slow or impaired growth may therefore be an adaptation to survive phagocytosis.

The similarity in transcriptional regulation of the *vapA* and *vcgAB* operons is borne out in the similarity of the  $P_{vapA}$  and  $P_{vcgA}$  promoter sequences, which resemble promoters dependent on the principal sigma factor HrdB of *S. coelicolor* (Buttner *et al.*, 1990; Kang *et al.*, 1997). The promoter of the *virR* operon is also similar to these sequences, albeit to a lesser extent (Byrne *et al.*, 2007; Russell *et al.*, 2004). This suggests that these three *R. equi* promoters are dependent on the principal sigma factor of *R. equi*. Interestingly, the internal  $P_{orf5}$  promoter located within the *virR* operon (Fig. 2) is completely different, suggesting the involvement of an alternative sigma factor (Byrne *et al.*, 2007).

The pathogenicity islands of the equine *vapA* and porcine *vapB* plasmids have undergone extensive rearrangements. These are probably associated with the host tropism of strains harbouring the plasmids following acquisition of the pathogenicity island by an ancestral rhodococcal plasmid (Letek *et al.*, 2008). The *vcgB* gene, located downstream of

the *virR* operon, is conserved in both the *vapA* plasmid and the *vapB* plasmid (Letek *et al.*, 2008). Unlike *vcgA*, *vcgC* and the *vap* genes, *vcgB* has homologues in other bacterial species, which, with the exception of *M. smegmatis*, are all pathogenic mycobacteria that infect phagocytic cells. A recent analysis of the genome of *M. abscessus*, a fast-growing pathogenic species, revealed that in addition to the presence of mycobacterial virulence genes, the genome has acquired genes associated with pathogenicity from non-mycobacterial species, most notably from other actinobacteria, including *Rhodococcus* sp. (Ripoll *et al.*, 2009). The presence of near-identical plasmids in *M. marinum* and *M. abscessus* indicates that lateral gene transfer between fast- and slow-growing mycobacteria may occur (Ripoll *et al.*, 2009). However, the phylogeny of the mycobacterial *vcgB* genes resembles that of the 16S rRNA gene (Devulder *et al.*, 2005), indicating a vertical transmission of *vcgB* from a common mycobacterial progenitor species. In contrast, the rhodococcal *vcgB* genes are within a pathogenicity island that is located on a conjugative plasmid. As is the case for the pathogenicity island itself, the rhodococcal *vcgB* genes were most likely acquired via a lateral gene transfer event (Letek *et al.*, 2008, 2010; Takai *et al.*, 2000).

With the exception of *M. smegmatis*, *vcgB* has only been identified in mycobacterial species that infect phagocytic cells of a wide diversity of hosts, ranging from fish to mammals. The *vcgB* genes in these species survived reductive evolution of the genome that, for example, drove the emergence of *M. ulcerans* from *M. marinum* (Demangel *et al.*, 2009). The *R. equi* genome appears to be genetically stable, and not subject to extensive rearrangement or reductive evolution (Letek *et al.*, 2010). In contrast, the *R. equi* pathogenicity island has been subjected to extensive recent genetic rearrangements and gene corruption; for example, seven of the 23 pseudogenes in *R. equi* are located in the pathogenicity island, which represents only 0.5 % of the total genome (Letek *et al.*, 2008, 2010). While *vcgB* is conserved in both the *vapA* plasmid and the *vapB* plasmid, the flanking *vcgA* and *vcgC* genes are only present in the *vapA* plasmid. This conservation of *vcgB* in the *R. equi* pathogenicity islands, and within pathogenic mycobacterial species, suggests that this gene may play a role in the intracellular lifestyle of this group of pathogens important enough to resist corruption. This notion is strengthened by the observation that *vcgB* is induced following phagocytosis and remains transcribed at least 48 h following phagocytosis, during which *R. equi* proliferates. Furthermore, the coordinated regulation of the P<sub>*vcgA*</sub> and P<sub>*vapA*</sub> promoters supports a role for *vcgB* in infection. However, an *R. equi* *vcgB* mutant is not attenuated in a BALB/c mouse model (Ren & Prescott, 2004), indicating that under these experimental conditions, *vcgB* is not critical. The circumstances during the infection process that require *VcgB* therefore remain to be determined. Our current research aims to establish a function for *vcgB* and other pathogenicity island genes, and to elucidate the signal transduction pathways governing their expression.

## ACKNOWLEDGEMENTS

The authors thank Shinji Takai, Kitasato University, Towada, Japan, for making VapA monoclonal antibodies available. This work was supported by a grant from the Research Stimulus Fund of the Department of Agriculture, Fisheries and Food (RSF 06-379) and by a grant from Science Foundation Ireland (grant no. 02/IN.1/B203).
